

Certificates of optimality: the third way to biproportional apportionment

Abstract

The biproportional apportionment problem (BAP) must be faced in many proportional electoral systems where seats must be allocated to parties within regions. In Italy for instance, the electoral law contains incorrect procedures for solving this problem, which have resulted in inconsistent outcomes and violations of the Constitution in 3 out of the 5 last political elections. The fact is that BAP is non trivial, and only mathematically sophisticated algorithms relying on the machinery of network optimization and matrix scaling are currently available for solving it. The issue is: can they become an actual law? Citizens rightly demand simple, easy to understand, voting systems. However, the task of finding simple algorithms for solving BAP is quite challenging. The alternative seems to have simple, but unsound electoral laws. We propose the following way out of this dilemma: leave to a mathematically sophisticated algorithm the task of producing an optimal apportionment, but attach to it a “certificate of optimality”, that is, describe a simple procedure whereby anybody can check, through some elementary operations, that the seat allocation output by the algorithm indeed satisfies all the requirements for an apportionment, and that it is “as proportional as possible” to the vote matrix. We discuss one such certificate, based on the max flow-min cut Theorem, relative to a strongly polynomial parametric max flow method of ours for solving BAP.

1 Introduction

Electoral systems are usually quite complex, and they are assembled out of many interacting components, which must be properly designed in order to achieve consistency and efficiency in the overall system. Sometimes it happens that designing a certain component is a highly nontrivial task. Mathematics can be of invaluable help in providing sound designs whose complexity escapes simple-minded procedures. As a matter of fact, when the latter are employed in order to solve an inherently difficult problem, severe inconsistencies and anomalies may occur. Therefore, there are actual cases where the use of mathematics is unavoidable.

However, it may happen that only mathematically sophisticated algorithms are available for solving a certain design problem. Are they “writable” as an actual law? Citizens rightly demand simple, easy to understand, voting systems (Principle 1 in the so-called “Erice Decalogue” [17]). Then the following dilemma may arise:

Which is better? To have simple, but unsound electoral laws, or sound, but complex ones?

In this paper, we propose the following way out:

Leave to a mathematically sophisticated algorithm the task of PRODUCING a sound solution, but attach to it a certificate of guarantee, that is, describe a simple procedure whereby ANYBODY CAN CHECK, through some elementary operations, that the solution output by the algorithm indeed satisfies all the requirements sought for.

In the present paper we shall demonstrate this “third way” on a specific electoral design problem: biproportional apportionment. In many proportional electoral systems where several parties are in competition and the territory is subdivided into constituencies or regions, it is important to know how the seats are allocated to the parties within the regions. The problem of seat allocation to the parties within the regions is present in several countries, e.g. Germany, Italy, Mexico, Switzerland, Belgium, Denmark, Iceland, Faroe Islands, etc.

A well-known formulation of the above seat allocation problem (see, e.g., [2]) is as follows. Each region is granted a certain number of seats. This number is determined before the election on the basis of the region’s population. Then each party is granted a certain number of seats at the national level. This number is determined after the election on the basis of the total number of votes obtained by the party. Then, given

- (a) a matrix of votes obtained by each party in each region;
- (b) the total number of seats apportioned to each region;
- (c) the total number of seats granted to each party;

one has to find a matrix of seats allocated to each party within in each region. Such matrix must satisfy the following conditions:

- (i) all of its entries must be nonnegative integers;
- (ii) the sum of the seats assigned to all parties within a given region must be equal to the number of seats in the region;
- (iii) the sum of the seats awarded to a given party in all regions must be equal to the total number of seats for the party.
- (iv) if a party receives no vote in some region, it cannot receive seats in that region;
- (v) the matrix of seats should be “as proportional as possible” to the matrix of votes.

A matrix satisfying conditions (i)–(iv) is called an *apportionment*. The requirement (v) needs a formal specification. The way this is done leads to different approaches in the literature. The above stated problem is called a *biproportional apportionment problem* (BAP).

Perhaps not suprisingly, there are some electoral laws which fail to produce a correct procedure for solving BAP. For instance, Balinski and Ramírez [5] discovered a bug in the Mexican electoral law, which was later fixed. A similar bug turns out to occur in the current Italian law and this has not been fixed yet [11, 12, 13, 14].

On the other hand, mathematically sound procedures for BAP are indeed available. In two milestone papers [3, 4], Balinski and Demange characterized proportionality between real or integral matrices in terms of a set of axioms. It turns out that, for any given rounding rule, there is a unique apportionment

satisfying the stated axioms. The algorithm for computing the apportionment calls for a sequence of scaling and rounding operations on the vote matrix, where rounding usually means to the lower, to the upper, or to the closest integer.

There are many sound procedures for BAP which have been later proposed. We mention the Discrete Alternate Scaling Method (DAS)[15, 9], the convex separable formulation of BAP by Gaffke and Pukelsheim [7, 8], the minimax parametric network flow method by Serafini and Simeone [16]. All these procedures share quite a degree of mathematical sophistication and so it is problematic to embody them in a real-life electoral law.

Formally the problem we want to solve is as follows. Before the elections the following data are given: a set M of electoral regions, integer numbers r_i , $i \in M$, (seats assigned to region i), with $H := \sum_{i \in M} r_i$ (house size), a set N of parties. After elections integer numbers p_j , $j \in N$, and rational numbers q_{ij} , $i \in M$, $j \in N$, are computed from the votes. Let also Z be the set of pairs (i, j) such that party j has received zero votes in region i . The numbers p_j are the seats assigned to party j at national level and the numbers q_{ij} , called *target quotas*, correspond to the ideal seats to be assigned in region i to party j . We do not make any assumption on how the target quotas are computed, apart from setting $q_{ij} = 0$ if $(i, j) \in Z$. Similarly we do not make any assumption on how the seats p_j are computed, apart from the condition $\sum_j p_j = H$.

From these data we have to compute the actual seats x_{ij} to be assigned in region i to party j such that

$$\sum_{i \in M} x_{ij} = p_j, \quad j \in N, \quad \sum_{j \in N} x_{ij} = r_i, \quad i \in M, \quad x_{ij} = 0, \quad (i, j) \in Z. \quad (1)$$

and the error, defined as the maximum absolute deviation from the target quotas,

$$\tau := \max_{ij} |x_{ij} - q_{ij}| \quad (2)$$

is minimized. Any solution satisfying (1) is obviously a biproportional apportionment. The apportionment is *optimal* if it minimizes (2). The problem of finding an optimal biproportional apportionment problem can be modeled as the following parametric capacitated transportation problem.

$$\begin{aligned} \tau^* = \min \quad & \tau \\ & \lceil q_{ij} - \tau \rceil^+ \leq x_{ij} \leq \lfloor q_{ij} + \tau \rfloor & (i, j) \notin Z \\ & x_{ij} = 0 & (i, j) \in Z \\ & \sum_{i \in M} x_{ij} = p_j & j \in N \\ & \sum_{j \in N} x_{ij} = r_i & i \in M \end{aligned} \quad (3)$$

where $\lceil a \rceil^+ = \max\{0, \lceil a \rceil\}$. As explained in [16] the solution of (3) can be efficiently computed by solving a sequence of Max Flow problems. In this paper we are not concerned with algorithmic issues related to solving (3). Rather we want to develop a “certificate of optimality” for the optimal apportionment of (3). Even a layman with some very elementary computing skills can ascertain that the seat allocation produced by the above algorithm is indeed a feasible apportionment, and that there is no feasible apportionment with a smaller error (defined as in (2)), i.e. it minimizes the maximum absolute error of the apportionment w.r.t. some pre-specified (but arbitrary) “target quotas”. Our certificate relies on the Max flow–Min cut Theorem of network flows, but this fact can be totally ignored by the layman.

Our paper is structured as follows. In Section 2 we provide an informal introduction to the notion of certificate of optimality under the form of a medieval tale. Section 3 lays out the theoretical foundations of our certificate and provides an example referring to the Italian political elections in 2008. The notion of certificate can be extended to all region-party pairs and this will be discussed in Section 4. Section 5 finally, briefly offers some conclusions.

2 A medieval tale

Virgil: It was brought to my knowledge that you have been appointed by the Township of Siena as the Official Verifier of their next elections.

Dante: You speak the truth, but I fear that also this time the electoral system adopted by the Township will produce inconsistencies and paradoxes.

Virgil: What happened?

Dante: Last time the Contrada (ward) Bruco got 4 seats, instead of the 5 granted to it by the Township Edict, while Contrada Oca got 2 seats instead of 1.

Virgil: I think I can do something for you. I know that one Pisan mathematician, named Leonardo Fibonacci, has left a booklet where he describes a correct method for your type of elections. Surely, his method will not give rise to the inconveniences you have complained about.

Dante: Looks interesting, but I am worried that the mathematical subtleties of his method will make the Elders of the Township quite suspicious and that eventually they will refrain from approving it.

Virgil: Don't worry. I happen to own a secret manuscript where Leonardo gives detailed explanations about how even a layman can check that the outcome of his method is correct.

Three months later

Dante: As instructed by you, I have handed you the table of votes obtained by the 6 parties in the 5 wards of Siena, together with the number of seats at stake in each ward (Table 1), and I got back from you a table of seats allocated to the parties in the wards according to Leonardo Fibonacci's method (Table 2).

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Seats
Aquila	4960	4350	850	4970	4940	4930	5
Bruco	2300	2900	4955	4965	4945	4935	5
Civetta	0	0	0	4950	0	50	1
Drago	0	0	0	2205	0	2795	1
Oca	0	0	0	700	4300	0	1

Table 1:

Virgil: The last row of the table shows, for each party, the total number of seats attributed to the party in the whole township. It was obtained through a preliminary computation prior to the distribution of seats to parties within the wards.

Dante: No objection to the last row. In order to check it, I have completed my table (Table 3) with the total number of votes in each ward (row-sums) and for each party (column-sums).

Then the Bottai party, with its 7260 votes, gets almost 11.17 % of the votes, since $7260/65000 = 11.1692$; thus, it should get also 11.17 % of the 13 seats, that is, 1.452 seats. Proceeding this way, I have computed

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Seats
Aquila	1			2	1	1	5
Bruco		1	1	1	1	1	5
Civetta				1			1
Drago						1	1
Oca					1		1
Seats	1	1	1	4	3	3	13

Table 2:

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Total	Seats
Aquila	4960	4350	850	4970	4940	4930	25000	5
Bruco	2300	2900	4955	4965	4945	4935	25000	5
Civetta	0	0	0	4950	0	50	5000	1
Drago	0	0	0	2205	0	2795	5000	1
Oca	0	0	0	700	4300	0	5000	1
Total	7260	7250	5805	17790	14185	12710	65000	13

Table 3:

the exact number of seats that each party deserves (Table 4)

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Total
Exact quotas	1.452	1.45	1.161	3.558	2.837	2.542	13

Table 4:

Virgil: The numbers you have computed are actually known as exact (or natural) quotas. Unfortunately, you cannot assign to a party a fractional number of seats. So, your exact quotas must be replaced by integer approximations.

Dante: That part is clear, and I see also how it is done in Leonardo's method. Each party is preliminarily assigned the integer part of its exact quota, for a total of 10 seats. The 3 remaining seats are assigned to the 3 parties with the largest decimal parts, that is, to the Sediari party with decimal part 0.837, to the Mugnai party with decimal part 0.558 and to the Vasari party with decimal part 0.542. In this way, one obtains the total number of seats attributed to the individual parties as shown in Table 2. It looks quite reasonable to me.

Virgil: What you have just described is known as the Largest Remainders Method.

Dante: I have tried to apply this method ward by ward. For example, in the Aquila ward the Bottai party gets 19.84 % of the votes, since $4960/25000 = 0.1984$; so it should obtain 19.84% of the 5 available seats, that is, 0.992 seats. In this way I have computed the table of (wardwise) exact quotas (Table 5).

From that table I went on and computed, ward by ward, the number of seats to be assigned to the 6 parties by what you call the Largest Remainders method (Table 6).

But I was very disappointed, since some column sums were wrong: not always the sum of the seats given to a party in the different wards did match the total number of seats granted to that party. Actually, the Cestari party got one seat in excess, while the Mugnai party got one seat less. I can also add that I did

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari
Aquila	0.992	0.870	0.170	0.994	0.988	0.986
Bruco	0.460	0.580	0.991	0.993	0.989	0.987
Civetta	0	0	0	0.990	0	0.010
Drago	0	0	0	0.441	0	0.559
Oca	0	0	0	0.140	0.860	0

Table 5:

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Seats
Aquila	1	1		1	1	1	5
Bruco		1	1	1	1	1	5
Civetta				1			1
Drago						1	1
Oca					1		1
Seats	1	2	1	3	3	3	13
Granted Seats	1	1	1	4	3	3	13

Table 6:

again this computation proceeding party by party and assigning the seats to the wards. Yet, I could find the same type of wrong sums, this time on the rows.

On the other hand, I have checked that in the Leonardo's table both row- and column-sums are indeed correct. Namely, I have verified that such table meets the following requirements:

- (i) For each ward, the sum of the seats attributed to the 6 parties within that ward (row-sum) is equal to the number of seats at stake in that ward;
- (ii) For each party, the sum of the seats attributed to the party in the 5 wards (column-sum) is equal to the number of seats granted to that party;
- (iii) If a party gets no votes in a ward, it cannot receive any seat in that ward.

Virgil: For the sake of brevity, let us refer to a table of (integer) seats satisfying properties (i), (ii), and (iii) as an apportionment.

Dante: But I am puzzled by something strange. All exact quotas lying between 0 and 1, I would expect to see an apportionment where each entry is rounded either down to 0 or up to 1. Instead the exact quota of the Mugnai party in the Aquila ward, i.e. 0.994, is approximated by 2 !

Virgil: There is no mistake. As a matter of fact, no matter how the exact quotas of Table 5 are rounded up or down, one can never get an apportionment satisfying all the requirements (i), (ii), and (iii).

Dante: How can you possibly make such a statement? The number of alternative ways to round up or down the 18 fractional entries of Table 5 is a huge number! How can you be sure that none of them gives rise to an apportionment?

Virgil: Be patient, and I will offer you an indisputable argument. But allow me to preliminarily make some simple considerations about approximating fractional numbers by integer ones. If you approximate the number 5 by 8 (which is 3 units above 5) or by 2 (which is 3 units below 5), in both cases the error you make amounts to 3. Prescribing a maximum error of 3 with respect to 5 is tantamount to require that the approximating number lies in the interval between 2 and 8. Similarly, prescribing a maximum error

of 4.25 w.r.t. 9.5 is equivalent to require that the approximating number lies in the interval $5.25 - 13.75$. If in addition you know that the approximating number is an integer, you can restrict the interval to $6 - 13$. Are you following me?

Dante: Perfectly.

Virgil: Now, suppose I claim that the maximum error of Leonardo's apportionment (Table 2) w.r.t. the exact quotas (Table 5) is 1.006. How would you check my claim?

Dante: That's easy! Comparing Tables 2 and 5, I would compute a table of errors (Table 7), which shows that the maximum error is indeed 1.006.

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari
Aquila	0.008	0.870	0.170	1.006	0.012	0.014
Bruco	0.460	0.420	0.009	0.007	0.011	0.013
Civetta	0	0	0	0.010	0	0.010
Drago	0	0	0	0.441	0	0.441
Oca	0	0	0	0.140	0.140	0

Table 7:

Virgil: For future purposes, let us double check on that. If the maximum error is 1.006, then in each cell of Table 2 the entry should lie in the interval between (exact quota $- 1.006$) and (exact quota $+ 1.006$). Notice that since in this case all fractional entries are smaller than 1.006, and since on the other hand seats are always nonnegative, we can safely set to 0 the lower extreme of the interval. Hence all entries of Table 2 should lie in the intervals indicated in Table 8, and there should be at least one entry with error 1.006, making the entry coincide with its upper limit. and, since the seats must be integers, one can get the following tighter limits (Table 9).

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari
Aquila	0 - 1.998	0 - 1.876	0 - 1.176	0 - 2.000	0 - 1.994	0 - 1.990
Bruco	0 - 1.466	0 - 1.586	0 - 1.997	0 - 1.999	0 - 1.995	0 - 1.993
Civetta				0 - 1.996		0 - 1.016
Drago				0 - 1.447		0 - 1.565
Oca				0 - 1.146	0 - 1.866	

Table 8:

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari
Aquila	0 - 1	0 - 1	0 - 1	0 - 2	0 - 1	0 - 1
Bruco	0 - 1	0 - 1	0 - 1	0 - 1	0 - 1	0 - 1
Civetta				0 - 1		0 - 1
Drago				0 - 1		0 - 1
Oca				0 - 1	0 - 1	

Table 9:

Dante: Yes, I can see that the entries of Table 2 are within the intervals of Table 9, and that the number

of seats attributed to the Mugnai party in the ward Aquila is equal to the upper limit 2, with an error 1.006 w.r.t. the exact quota 0.994. But couldn't there exist an apportionment whose maximum error is below 1.006?

Virgil: Let me convince you that no such apportionment may exist. From this it will ensue that Leonardo's apportionment is the best you can get, since it is impossible to decrease the maximum error of an apportionment. The crucial observation is the following. Look at the upper limit for Mugnai party in the Aquila ward in Table 9. Recall that this upper limit is $2 = 0.994 + 1.006$, where 0.994 is the exact quota. Now, suppose that the maximum error becomes smaller than 1.006. Then the upper limit becomes smaller than 2, and thus in Table 9 the upper limit of said cell becomes 1. All the other positive upper limits remain equal to 1. Let me argue that there cannot be any apportionment satisfying all the limits in Table 9, with the upper limit 2 replaced by 1. Notice that all entries of such an apportionment must be either 0 or 1, since the only integers in the interval $0 - 1$ are 0 and 1. By the way, this will provide a negative answer to your previous question on whether one can get an apportionment by suitably rounding down to 0 or up to 1 the fractional exact quotas in Table 5.

Let me distinguish among the wards a set of wards of the Sun and a set of wards of the Moon. The Sun wards are Aquila and Bruco, the remaining wards are of the Moon. Similarly, let me call parties of the Sun the Bottai, Cestari, and Fabbri, and the remaining be the parties of the Moon. Now tell me: what is the largest number of seats within wards of the Sun that can be assigned to parties of the Moon?

Dante: Surely 6, because in either ward of the Sun one can assign at most 1 seat to each of the 3 Moon parties.

Virgil: Very good. Next: what is the least number of seats that can be attributed in Sun wards to Sun parties?

Dante: Obviously 4, since out of the 10 seats at stake in the 2 Sun wards at most 6 can go, as I said, to Moon parties. But now I see the contradiction which does not consent to it, since on the one hand the 3 Sun parties must collectively get at least 4 seats: on the other hand they are altogether granted only 3 seats (one seat each). Summing up, I agree on the fact that Leonardo's table provides a best apportionment, and I will recommend it to the Elders.

Virgil: I am quite confident that the Elders, though not profound in Mathematics as Leonardo, will be convinced by these common sense arguments. But now tell me: is it true that you are always eager of complete explanations?

Dante: Yes indeed, I am not satisfied until I have the whole picture in front of me.

Virgil: And is it true that you might be asked again to serve as the Official Verifier in some future election?

Dante: Yes, it might happen.

Virgil: Then there is one more thing to say.

Dante: What do you mean by this? Are you unfolding some hidden truth?

Virgil: No hidden truth. The only fact is that I applied Leonardo's arguments to this very special election in which the Bottai, Cestari and Fabbri parties received no votes in the Civetta, Drago and Oca wards. But suppose there were some votes and so the possible smallest and largest number of seats could be different from zero.

Dante: What consequence would this fact provoke?

Virgil: The consequence is that you cannot draw the conclusion that the Sun parties must receive 3 seats in the Sun wards. You should first consider the *least* number of seats that the Sun parties can receive

in the Moon wards. This number would in turn give you the largest number of seats for the Sun parties in the Sun wards, and, if this number is smaller than the previous number which gave you the smallest number of seats, this clearly establishes a contradiction. Are you convinced by these arguments?

Dante: Yes, I am convinced.

Virgil: But my impression is that there is still something puzzling you. What are you actually thinking?

Dante: Your explanations are very clear to me, but I am wondering whether it was only a lucky circumstance that you could find this division of parties and wards into Sun and Moon. I can see that by renaming Sun and Moon other groups of parties and other groups of wards there is no contradiction arising. How could I be sure that in another election a similar argument can be presented to the Elders? I realize that it requires the ability of a mathematician like Leonardo to find the right apportionment and the division of Sun-Moon parties and wards, but does this division exist in any case?

Virgil: Your intelligence has never disappointed me and I am glad that you have raised this question. In the secret manuscript by Leonardo it is also proved (and I am afraid it will take centuries before the mathematicians will rediscover this truth) that such division is always granted.

Dante: Now I am fully satisfied by your explanations and I am very grateful to you. Once more you are my real Guide and Master.

One month later:

Virgil: Have you been able to convince the Elders of the correct seat assignment?

Dante: Yes, everything went smoothly and the Elders praised a lot my arguments. Unfortunately after one week the Cestari party started complaining about their seat assignment. They were granted only one seat which, according to Leonardo's table, was given in the Bruco ward, but due to some obscure reasons they prefer this seat in the Aquila ward. They argue that having a quota of 0.87 in the Aquila ward and 0.42 in the Bruco ward, their seat should be assigned in the Aquila ward. The question is on the hands of the Elders which are about to summon me again to settle the question.

Virgil: So, how do you think of settling the matter?

Dante: I do not know really. I thought that I could use the same arguments and so I prepared a new table of limits, like the one we did before (Table 9). This time however, I thought I had to keep the high error for the Mugnai party in the Aquila ward and leave the interval as 0-2. Indeed we already proved that it was not possible to narrow this interval to 0-1.

Virgil: Yes, you did correctly.

Dante: Then in the new table I brought the interval for the Cestari party in the Aquila wards to 1-1, exactly to meet their request. But at the same time I did not feel like allowing an error of 0.992 to the Bottai party in the Aquila ward. Since 0.992 is larger than 0.87 it seems unfair to lower one error at the expense of an even larger error for others. Hence the interval for the Bottai party in the Aquila ward is 1-1.

Virgil: This is perfectly reasonable.

Dante: And the same is true for all other ward-party pairs with error larger than 0.87. So this is the table (Table 10) I have obtained:

Virgil: It looks correct.

Dante: But now you can see! This time I do not find any contradiction in computing as before the possible seats. The Aquila and Bruco wards are entitled at least $10-7=3$ seats, and this does not lead to

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari
Aquila	1 – 1	1 – 1	0 – 1	0 – 2	1 – 1	1 – 1
Bruco	0 – 1	0 – 1	1 – 1	1 – 1	1 – 1	1 – 1
Civetta				1 – 1		0 – 0
Drago				0 – 1		0 – 1
Oca				0 – 1	0 – 1	

Table 10:

a contradiction.

Virgil: Of course you cannot find the contradiction in this way. You need a different group of Sun and Moon parties and wards. My suggestion is that you try with only Bruco as a Sun ward and the Bottai and Cestari as Sun parties.

Dante: So let me try this way. In the Bruco ward 5 seats are at stake. At most 4 seats can be assigned to the Moon parties (Fabbri, Mugnai, Sediari and Vasari) and therefore at least one seat must be assigned between the Bottai and Cestari parties. And then ... it looks there is no contradiction because they have to receive two seats after all.

Virgil: Remember what I have told you last time. There is another symmetrical consideration to take care of.

Dante: Sure, now I remember. In the Moon wards (Aquila, Civetta, Drago, Oca) at least 2 seats must be assigned to the Sun parties so the Sun parties can receive in the Sun wards at most $2-2=0$ seats. Here there is the contradiction! Now I can safely report to the Elders that the Cestari request cannot be fulfilled.

3 A global certificate

Let us call ‘Solver’ the person who actually solves the biproportional apportionment problem described in Section 1 and ‘Verifier’ the person who has to check the validity of the solution provided by the Solver. For the Verifier to check the validity, the Solver has to provide also a certificate, which consists in a subset I of regions (let \bar{I} be the complementary subset) and a subset J of parties (let \bar{J} be the complementary subset). These subsets, together with the given solution x_{ij}^* and corresponding absolute error τ^* , enable the Verifier to check the validity of the solution through some elementary steps. Indeed the only mathematical “skills” required to the Verifier are:

- (1) to be able to perform ordinary sums and subtractions;
- (2) to be able to compare two numbers to tell whether one of them is smaller than or equal to the other;
- (3) to know the meaning of $\lfloor a \rfloor$, $\lceil a \rceil$ and $\lceil a \rceil^+$ for a given (rational) number a and to be convinced of

the two following simple facts:

- (a) for any number a , $\lfloor a \rfloor \leq a$ and $\lceil a \rceil \geq a$,
- (b) if x is an integer, then $a \leq x \leq b$ if and only if $\lceil a \rceil \leq x \leq \lfloor b \rfloor$,
if x is a nonnegative integer, then $a \leq x \leq b$ if and only if $\lceil a \rceil^+ \leq x \leq \lfloor b \rfloor$,
- (c) if a and b are numbers such that $a \leq b$, then $\lfloor a \rfloor \leq \lfloor b \rfloor$ and $\lceil a \rceil \leq \lceil b \rceil$,
(it is implied by (a) and (b)),
- (d) if b is integer and $b' < b$, then $\lfloor b' \rfloor \leq b - 1$,
If a is an integer and $a' > a$, then $\lceil a' \rceil \geq a + 1$.

Then the Verifier, equipped with these basic skills, should first

– check that $\sum_{i \in M} x_{ij}^* = p_j$, $\sum_{j \in N} x_{ij}^* = r_i$, $x_{ij}^* = 0$ for $(i, j) \in Z$ and $\tau^* = \min_{ij} |x_{ij}^* - q_{ij}|$, that is, x^* is a feasible apportionment and its error is the one claimed (skills 1 and 2).

Next the Verifier, in order to be convinced that there can be no apportionment with error $\tau < \tau^*$, should first:

- compute $\alpha_{ij} := \lceil q_{ij} - \tau \rceil^+$, with $i \in \bar{I}$ and $j \in J$, $\beta_{ij} := \lfloor q_{ij} + \tau \rfloor$, with $i \in I$ and $j \in \bar{J}$, if $(i, j) \notin Z$ ($\alpha_{ij} = \beta_{ij} = 0$ if $(i, j) \in Z$) (skill 1);
- compute $\bar{\alpha} := \sum_{i \in \bar{I}} \sum_{j \in J} \alpha_{ij}$ and $\bar{\beta} := \sum_{i \in I} \sum_{j \in \bar{J}} \beta_{ij}$ (skill 1).

and then reason as follows:

- if the maximum absolute error with respect to the target quotas over all seat assignments is τ , then every seat assignment x_{ij} must lie in the interval $[q_{ij} - \tau, q_{ij} + \tau]$ (skill 2) and this interval, due the integrality and nonnegativity of x_{ij} can be equivalently restricted to $[\lceil q_{ij} - \tau \rceil^+, \lfloor q_{ij} + \tau \rfloor] = [\alpha_{ij}, \beta_{ij}]$ (skill 3(b));
- if an apportionment x with maximum absolute error τ is required, then the largest number of seats which can be assigned to parties in \bar{J} in regions in I is $\bar{\beta}$ and consequently the smallest number of seats which can be assigned to parties in J in regions in I is $\sum_{i \in I} r_i - \bar{\beta}$ (refer to Fig. 1(a) which represents the table of seats; the rows are the regions and the columns are the parties; in the figure $R := \sum_{i \in I} r_i$) (skills 1 and 2);
- similarly, if an apportionment x with maximum absolute error τ is required, then the smallest number of seats which can be assigned to parties in J in regions in \bar{I} is $\bar{\alpha}$ and consequently the largest number of seats which can be assigned to parties in J in regions in I is $\sum_{j \in J} p_j - \bar{\alpha}$ (refer to Fig. 1(b) where $P := \sum_{j \in J} p_j$) (skills 1 and 2);
- finally, if

$$\sum_{j \in J} p_j - \bar{\alpha} < \sum_{i \in I} r_i - \bar{\beta}$$

that is, the largest number of seats is less than the smallest number of seats, then it is impossible to have an apportionment with error τ (skill 2). It is also impossible to have an apportionment with any smaller error because $\bar{\beta}$ decreases and $\bar{\alpha}$ increases if τ decreases (skill 3(c)).

In order to be convinced of the validity of the previous statements, only elementary reasoning is required. Note that the mathematical techniques to get the optimal solution can be totally ignored by the Verifier.

The existence of subsets I and J for which $\sum_{j \in J} p_j - \bar{\alpha} < \sum_{i \in I} r_i - \bar{\beta}$ if $\tau < \tau^*$ is established by Gale's theorem [1, 10] which states that there exists a feasible flow in a network if and only if for each subset of nodes the net flow out of the subset must be not larger than the cut capacity induced by the node subset.

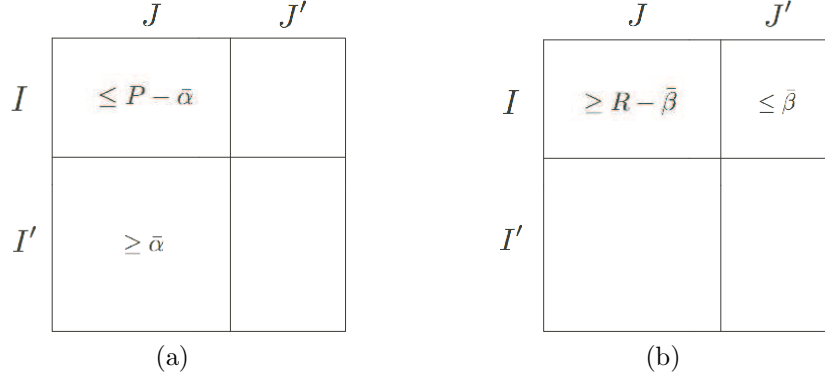

Figure 1:

Since the problem (3) is equivalent to a flow problem with M a set of sources r_i and N a set of sinks p_j , then $\sum_{i \in I} r_i - \sum_{j \in J} p_j$ is the net flow out of the node subset $I \cup J$ and $\bar{\beta} - \bar{\alpha}$ is the cut capacity. The computation of the subsets is carried out by standard max flow techniques.

The above procedure “challenges” the Verifier to check the certificate for any trial $\tau < \tau^*$. However, the Verifier might be still in doubt whether there is a “feasible” error between the largest τ ever checked and τ^* . The following additional argument shows that it is enough to ascertain the nonexistence of a feasible apportionment for a single set of bounds.

First the Verifier has to check the feasibility of the given apportionment and that its error is τ^* . During this computation he has also to list the pairs of indices (h, k) , such that $\tau^* = |x_{hk}^* - q_{hk}|$. Let us call these pairs *critical*. For any critical pair we have

$$\begin{aligned} &\text{either } i) \quad x_{hk}^* = q_{hk} - \tau^* \\ &\text{or } ii) \quad x_{hk}^* = q_{hk} + \tau^* \end{aligned}$$

We may say that in case *i*) the critical pair (h, k) is a *lower pair* and in case *ii*) it is an *upper pair*. In other words $q_{hk} - \tau^*$ is integral for a lower pair and $q_{hk} + \tau^*$ is integral for an upper pair.

In the medieval tale of Sec. 2, there is only one critical pair (h, k) , namely, the upper pair (Aquila, Mugnai), with $2 = x_{hk}^* = q_{hk} + \tau^* = 0.994 + 1.006$. When the maximum error τ becomes smaller than τ^* , $q_{hk} + \tau$ becomes strictly smaller than 2. Therefore, the upper bound on the (integer) number of seats x_{hk} cannot be larger than 1. But already the upper bound 1, the other bounds being unchanged, makes the BAP infeasible.

Now the Verifier has to notice that, among the critical pairs, there is one such that, if it is a lower pair then $h \in \bar{I}$ and $k \in J$, whereas if it is an upper pair then $h \in I$ and $k \in \bar{J}$. Let us call any such critical pair a *blocking pair*. The Verifier does not need to be convinced that a blocking pair does indeed exist. He has only to scan all pairs (i, j) until he finds a blocking pair.

Then the Verifier is asked to compute the $\alpha_{ij}(\tau^*)$ and $\beta_{ij}(\tau^*)$ values w.r.t. the error τ^* , for the same sets I and J . Here we have explicitly denoted the dependance of these values on τ . Now the Verifier is invited to think what happens to $\alpha_{ij}(\tau)$ and $\beta_{ij}(\tau)$ for an error $\tau < \tau^*$. Since $\alpha_{ij}(\tau) = \lceil q_{ij} - \tau \rceil^+$ and $q_{ij} - \tau > q_{ij} - \tau^*$, then by skill 3(c) we have $\alpha_{ij}(\tau) \geq \alpha_{ij}(\tau^*)$. Similarly, from $\beta_{ij}(\tau) = \lfloor q_{ij} + \tau \rfloor$ and $q_{ij} + \tau < q_{ij} + \tau^*$, again by skill 3(c) we have $\beta_{ij}(\tau) \leq \beta_{ij}(\tau^*)$. These inequalities are clearly valid for all

pairs (i, j) .

The crucial point concerns the blocking pair. Here the Verifier needs the skill 3(d). Indeed if the blocking pair is lower, $q_{hk} - \tau^*$ is integral and nonnegative (it is just a seat number and cannot be negative). Hence for any $\tau < \tau^*$, $\lceil q_{ij} - \tau \rceil \geq \lceil q_{ij} - \tau^* \rceil + 1$, i.e. $\alpha_{hk}(\tau) \geq \alpha_{hk}(\tau^*) + 1$. Then the Verifier acknowledges that he has to use at least the lower bound $\alpha_{hk}(\tau^*) + 1$ for the lower blocking pair (h, k) if he wants to consider errors $\tau < \tau^*$.

If the blocking pair is upper we have that $q_{hk} + \tau^*$ is integral. Hence for any $\tau < \tau^*$, $\lfloor q_{ij} + \tau \rfloor \leq \lfloor q_{ij} + \tau^* \rfloor - 1$, i.e. $\beta_{hk}(\tau) \leq \beta_{hk}(\tau^*) - 1$. Then the Verifier acknowledges that he has to use at most the upper bound $\beta_{hk}(\tau^*) - 1$ for the upper blocking pair (h, k) if he wants to consider errors $\tau < \tau^*$.

Now the Verifier, equipped with the values $\alpha_{ij}(\tau^*) := \lceil q_{ij} - \tau^* \rceil^+$, with $i \in \bar{I}$ and $j \in J$, (i, j) not blocking, $\beta_{ij}(\tau^*) := \lfloor q_{ij} + \tau^* \rfloor$, with $i \in I$ and $j \in \bar{J}$, (i, j) not blocking, $\alpha_{ij} = \beta_{ij} = 0$ if $(i, j) \in Z$, and either $\alpha_{hk}(\tau^*) + 1$ for the lower blocking pair (h, k) or $\beta_{hk}(\tau^*) - 1$ for the upper blocking pair (h, k) , proceeds with the previous computations of $\bar{\alpha}$ and $\bar{\beta}$. He will eventually find the contradiction

$$\sum_{j \in J} p_j - \bar{\alpha} < \sum_{i \in I} r_i - \bar{\beta}$$

If the Verifier had used $\alpha_{ij}(\tau)$ and $\beta_{ij}(\tau)$ (instead of $\alpha_{ij}(\tau^*)$, $\beta_{ij}(\tau^*)$ and $\alpha_{hk}(\tau^*) + 1$ or $\beta_{hk}(\tau^*) - 1$) the contradiction would arise anyway because of the previously found inequalities $\alpha_{ij}(\tau) \geq \alpha_{ij}(\tau^*)$, $\beta_{ij}(\tau) \leq \beta_{ij}(\tau^*)$, $\alpha_{hk}(\tau) \geq \alpha_{hk}(\tau^*) + 1$, $\beta_{hk}(\tau) \leq \beta_{hk}(\tau^*) - 1$. Notice that these inequalities hold as equalities for any τ in a suitable left neighborhood of τ^* ; but the actual value of τ is irrelevant for the Verifier.

Sometimes the impossibility of an apportionment for a given error is due to a simple fact, which is almost self-evident and does not require a special mathematical knowledge. Although this kind of impossibility is only a particular case of the previous general case, it is however more convenient to deal with it separately, just because it is a certificate that does not need many explanations. Indeed if for a given party j it happens that

$$\text{either } \sum_{i \in M} \lfloor q_{ij} + \tau \rfloor = \sum_{i \in M} \beta_{ij} < p_j \quad \text{or} \quad \sum_{i \in M} \lceil q_{ij} - \tau \rceil^+ = \sum_{i \in M} \alpha_{ij} > p_j$$

then there is clearly no way of assigning seats in the regions for party j and reaching the prescribed national number of seats p_j . Similarly, if for a given region i it happens that

$$\text{either } \sum_{j \in N} \lfloor q_{ij} + \tau \rfloor = \sum_{j \in N} \beta_{ij} < r_i \quad \text{or} \quad \sum_{j \in N} \lceil q_{ij} - \tau \rceil^+ = \sum_{j \in N} \alpha_{ij} > r_i$$

then again there is no way of assigning seats in region i to the parties and reaching the prescribed regional number of seats r_i . We leave the reader to check that the four cases correspond to the following subset specifications:

$$\begin{aligned} p_j > \sum_{i \in M} \beta_{ij} &\implies I = M, & J = N \setminus \{j\}, \\ p_j < \sum_{i \in M} \alpha_{ij} &\implies I = \emptyset, & J = \{j\}, \\ r_i > \sum_{j \in N} \beta_{ij} &\implies I = \{i\}, & J = \emptyset, \\ r_i < \sum_{j \in N} \alpha_{ij} &\implies I = M \setminus \{i\}, & J = N. \end{aligned}$$

We apply these concepts to the results of the Italian political election (April 13-14, 2008) for the Chamber of Deputies. The target quotas in the 26 districts, already modified to take into account the majority bonus to the PDL party, are reported in Table 12. The regions are listed by rows and the parties by columns. The party acronyms are: PDL - Popolo della libertà, LN - Lega Nord, MPA - Movimento per le autonomie, PD - Partito democratico, IDV - Italia dei Valori, SVP - Südtiroler VolksPartei, UDC - Unione di Centro.

The seats assigned by the law to the regions, according to the population, before the elections are

$$r = \{24, 22, 40, 43, 15, 10, 29, 20, 13, 17, 43, 38, 9, 16, 40, 15, 14, 3, 33, 29, 44, 6, 22, 26, 28, 18\}$$

and the seats granted to the parties at the national level (according to the Largest Remainder Rule) are

$$p = p^N = \{272, 60, 8, 211, 28, 2, 36\}$$

As already pointed out in [11, 12, 13, 14, 16] the final seats assigned in each region *after* the election are different from the ones assigned by the law *before* the election. But this is only due to a flaw in the procedure of the Italian law. In our computation we have used the original r values. In the table the quotas have been rounded to three decimal digits.

We report in Table 13 the apportionment minimizing the maximum absolute error. Indeed we claim that it minimizes the maximum absolute error and we provide the following certificate to support our claim:

$$\begin{aligned} I = \{ & \text{Piemonte 1, Lombardia 2, Lombardia 3, Trentino-Alto Adige, Friuli-Venezia Giulia,} \\ & \text{Liguria, Toscana, Umbria, Lazio 2, Abruzzo, Molise,} \\ & \text{Campania 1, Campania 2, Puglia, Basilicata, Calabria, Sicilia 1} \} \\ J = \{ & \text{PDL, MPA, PD, IDV, SVP, UDC} \} \end{aligned}$$

The Verifier can compute the maximum error which is 0.75372 for the lower pair (Veneto 1, UDC) (1 seat against a target quota of 1.75372). Then, from the subsets I and J the α_{ij} and β_{ij} values can be computed by trying for instance an error $\tau = 0.7537$, as in Table 14, with α_{ij} , $i \notin I$, $j \in J$ on the left and β_{ij} , $i \in I$, $j \notin J$ on the right.

From the table the Verifier can deduce that the largest number of seats in (I, J) is given by 557 (total seats for parties in J) - 223 ($= \sum \alpha_{ij} = \bar{\alpha}$) = 334, and also that the smallest number of seats in (I, J) is given by 361 (total seats in regions in I) - 26 ($= \sum \beta_{ij} = \bar{\beta}$) = 335. Therefore it is impossible to have a solution with error $\tau = 0.7537$.

For the stronger form of verification, the Verifier needs to compute the $\alpha_{ij}(\tau^*)$ and $\beta_{ij}(\tau^*)$ values. These values are the same as in Table 14 with the exception of the lower blocking pair $(h, k) = (\text{Veneto 1, UDC})$ for which $\alpha_{hk}(\tau^*) = 1$ (instead of 2). Clearly, using in the computation of $\bar{\alpha}$, $\alpha_{hk}(\tau^*) + 1 = 2$ produces the same contradiction.

4 Strongly optimal solutions and individual certificates

By referring to the apportionment reported in Table 2 we may see that it is not the unique optimal solution. Indeed the solution in Table 11 is also optimal with the same error $\tau^* = 1.006$. We note that, although

	Bottai	Cestari	Fabbri	Mugnai	Sediari	Vasari	Seats
Aquila			1	2	1	1	5
Bruco	1	1		1	1	1	5
Civetta				1			1
Drago						1	1
Oca					1		1
Seats	1	1	1	4	3	3	13

Table 11:

the solution given in Table 11 cannot be improved for *all* pairs, it can be improved for some pairs without worsening the other pairs. In other words it is dominated.

With respect to the Table 2 the pairs which are different are: Aquila-Bottai passing from an error 0.008 to 0.992, Aquila-Fabbri from 0.17 to 0.83, Civetta-Bottai from 0.46 to 0.54, Civetta-Fabbri from 0.009 to 0.991. The other pairs are unchanged. Clearly the solution in Table 2 dominates the one in Table 11. Minimax solutions are typically non unique and among them there can be dominated solutions.

Hence we need to define a stronger form of optimality and provide a corresponding certificate of strong optimality for an apportionment x^* (see [16]). For a given region-party pair (h, k) , let $\tau_{hk}^* := |q_{hk} - x_{hk}^*|$ be the error for this pair. Let $L(h, k) := \{(i, j) \neq (h, k) : \tau_{ij}^* \leq \tau_{hk}^*\}$ be the set of pairs with error not larger than τ_{hk}^* , and let $U(h, k) := \{(i, j) : \tau_{ij}^* > \tau_{hk}^*\}$ be the complement set. Then we say that the apportionment x^* is *strongly optimal* if, for any pair (h, k) , there is no apportionment with error $\tau_{hk} < \tau_{hk}^*$, $\tau_{ij} \leq \tau_{hk}^*$ for $(i, j) \in L(h, k)$ and $\tau_{ij} \leq \tau_{ij}^*$ for $(i, j) \in U(h, k)$. Clearly strong optimality implies optimality.

The definition takes care of the fact that, while trying to improve the error for some pair (h, k) , it is not allowed to worsen those pairs which have a larger error than (h, k) . On the contrary, those pairs that have error less than or equal to (h, k) are allowed to worsen the error up to the ‘threshold’ τ_{hk}^* . Note also that if another pair exhibits the same error as (h, k) , the error for (h, k) is allowed to decrease without any decrease of the error for the other pair.

In [16] the uniqueness of the best apportionment is considered. The proposed procedure finds the so called unordered lexico-minimal solutions. If the fractional parts of the quotas are all different (or more exactly the values $q_{ij} - \lfloor q_{ij} \rfloor$ and $\lceil q_{ij} \rceil - q_{ij}$ are all different), then the lexico-min procedure described in [16] yields strongly optimal solutions. As shown in [16] it is highly unlikely that in a normal election two quotas have equal fractional parts.

Clearly a strongly optimal solution is robust with respect to any criticism and complaint parties might raise in order to gain more seats for themselves or to reduce seats for the other parties. More importantly, also strongly optimal solutions can be attached a certificate of optimality which can be checked against any complaint. We call this an *individual certificate*, since it is provided for each region-party pair. In contrast we may call *global* the certificate introduced in the previous section.

First note that no pair can have error less than $\bar{\tau}_{ij} := \min\{q_{ij} - \lfloor q_{ij} \rfloor ; \lceil q_{ij} \rceil - q_{ij}\}$. So, if $|q_{ij} - x_{ij}^*| = \bar{\tau}_{ij}$, or, more simply, if the error is no larger than one half, the apportionment cannot be improved for the pair (i, j) . Since this is obvious we need a certificate only for those pairs exhibiting an error larger than one half.

The individual certificate has the same features as the global certificate, that is, it specifies two subsets of regions and parties. It only differs in the way the values α_{ij} and β_{ij} are computed. According to the

definition of strong optimality, when we consider the pair (h, k) , we set the error values

$$\tau_{hk} < \tau_{hk}^*, \quad \tau_{ij} = \tau_{hk}^*, \quad (i, j) \in L(h, k), \quad \tau_{ij} := \tau_{ij}^* \quad (i, j) \in U(h, k)$$

from which we compute

$$\alpha_{ij} := [q_{ij} - \tau_{ij}]^+, \quad \beta_{ij} := [q_{ij} + \tau_{ij}]$$

Since by definition there is no apportionment with this error, in the parametric capacitated transportation problem (3) with capacities computed from τ there must exist, by Gale's theorem, a subset of nodes whose cut capacity is not large enough to accommodate the net flow out of the subset. This subset of nodes is clearly the certificate.

In the final part of the medieval tale the considerations to show that the Cestari party request cannot be fulfilled are indeed an individual certificate for the pair (Aquila, Cestari). As a second example reconsider the solution for the Italian election 2008 reported in Table 13. Although acknowledging that the best maximum error is 0.75372, the MPA party, having a quota of 1.626076, could claim 2 seats instead of 1 in the Sicily 1 region. To prove that MPA cannot receive 2 seats within the rules of a strongly optimal solution, we have in this case a very simple certificate. The MPA party is entitled globally 8 seats. However, it should receive at least 1 seat in Campania 1 (otherwise it would incur the higher error 1.00179). Similarly it should receive at least 1 seat in Campania 2, Puglia and Calabria respectively. For the same reason it has to get at least 3 seats in Sicily. This makes already 7 seats. Therefore it is impossible to have two seats in Sicily 1.

As a further example suppose that the PDL party is complaining about the 9 seats in Piemonte 2. Having a quota of 9.59563 the party claims 10 seats. The individual certificate for the pair (Piemonte 2, PDL) is given by the subsets:

$$I = \{\text{Sicily 1}\}, \quad J = \{\text{PDL, MPA}\}$$

from which we compute the α (on the left) and β (on the right) values as in the Table 15, from which we get the contradiction

$$\sum_{j \in J} p_j - \bar{\alpha} = 280 - 266 = 14 < \sum_{i \in I} r_i - \bar{\beta} = 26 - 11 = 15$$

5 Conclusions

In the design of sound electoral systems, some conflict may occur between accuracy and transparency. Indeed electoral problems like the biproportional apportionment one are not amenable to simple-minded solution, and when this is done several anomalies and paradoxes are likely to occur. On the other hand correct procedures may turn out to be too complex to be written down in an electoral law.

In this paper we have proposed a possible third way to get out of this dilemma. The key idea is to distinguish between the two stages of producing the solution and checking its validity. This idea is common in theoretical computer science, e.g. in the definition of the class NP. Luckily, for the particular min-max solution generated by the parametric max flow algorithm [16], this distinction is possible and a certificate can be produced on the basis of the Max Flow-Min Cut theorem. Obtaining such a certificate this way is not the task of the Verifier. However, it is nice to observe that its computation has low complexity.

While we have described a certificate with reference to biproportional apportionment similar ideas may have potential scope also in other contexts within the area, especially when writability is an important issue.

In conclusion, the adoption of a certificate of guarantee in presence of complex electoral rules which cannot be easily replicated by the layman, may result in better quality electoral systems without prejudice of transparency.
